

METHOD AND APPARATUS FOR
PRODUCING DIRECTIONALLY
SOLIDIFIED CASTINGS

FIELD OF THE INVENTION

The present invention relates to metal casting and can be used in producing castings with directional and single crystal structure. In particular the invention relates to a metal casting apparatus with a water-cooled tank having a truncated cone shape.

BACKGROUND OF THE INVENTION

5

An apparatus for directional solidification generally comprises a vacuum chamber inside which there are disposed a mold heating zone, a baffle system, a water-cooled chill plate usually made of copper, an induction furnace, and a thermocouple system that automatically controls and maintains the temperature in a cooling zone and in a heating zone within the furnace. Such features are disclosed in U.S. Patent Nos 3680625, 4804311, and 4412577.

10

Also known in the art is an apparatus for directional solidification, in which the cooling zone is a liquid cooling bath with a material that melts easily to serve the role of the cooling medium. The liquid metal bath is disclosed in U.S. Patent Nos 3763926 and 3915761, and Russian Federation Patent No 2010672.

15

Apparatuses in which both types of the above mentioned assemblies are combined (i.e., the copper chill plate and the liquid metal cooling bath) are also known. But those apparatuses comprise two actuators for vertical transportation of a mold with a metal casting. These actuators are disposed above and beneath the vacuum chamber housing. For that reason the dimensions of the apparatuses are enlarged and the service of the installations become complicated

20

- 2 -

while the reliability of the apparatuses is decreased (see U.S. Patent 5197531, and the publication Singer R.F. "Directional and Single Crystal Solidification Using LMC").

5 The closest prior art to the present invention is an
apparatus disclosed in French Patent Application 2604378, being
accepted as a prototype. This prototype apparatus comprises a
vacuum chamber with a heating member inside where there is
disposed a ceramic mold fixed on a water-cooled metallic plate which
is moved up and down with the help of a rod and of an actuator for
10 vertical transportation. A horizontal baffle separates a heating zone
and a cooling zone. In the cooling zone, concentrically with the chill
plate, there is disposed an additional circular water-cooled cavity with
the inner diameter exceeding the mold's maximal size. Below the
cavity there is disposed a container which is utilized for capturing the
15 poured casting metal in the event of mold breakage.

 The above apparatuses, including the prototype, can
function only when they comprise a crystallizer. It is impossible to use
such installation for directional solidification processing with a liquid
metal coolant and it is difficult to utilize the expensive alloys used in
20 directional solidification castings in the event of mold breakage. Thus
there is a need for a casting apparatus that provides a means that
efficiently cools the molten cast alloy while protecting the equipment
from damage in the event that the ceramic mold breaks while
containing the molten cast alloy material.

25 SUMMARY OF THE INVENTION

 The technical aim of this invention is to produce castings
having the directional and single crystal structure by the method of
radiation cooling without using the above-mentioned crystallizer.
Another aim of the invention is to be able to reconstruct easily the
30 invented apparatus for both radiation crystallization processing and
liquid metal cooling crystallization processing. The inventive apparatus

- 3 -

also increases the reliability and economic profit due to the apparatus' performance.

To achieve said aim the inventive apparatus comprises a vacuum chamber inside which there is disposed an induction melting
5 furnace, a mold preheating furnace with a ceramic mold, a drive assembly for mold transportation and a water-cooled tank. The drive assembly comprises a rod on which the mold is fixed with the help of a hanger and a regulating actuator for vertical movement being
10 positioned above the vacuum chamber. The water-cooled tank is shaped as a truncated cone. Its upper portion is opened towards the heating zone, and its bottom portion has a smaller base than the upper portion. A baffle separates the heating zone inside the induction furnace from the cooling zone; said baffle moves in a horizontal plane and closely adjoins the mold during the solidification process. It
15 consists of the segments or sectors (not less than 2 from each side).

BRIEF DESCRIPTION OF THE DRAWING

Fig.1 shows a schematic drawing of the apparatus where 1 is the ceramic mold, 2 is the hanger to fix the mold to the drive assembly, 3 is the rod, 4 is the heater of the mold preheating furnace,
20 5 is the heat baffle, 6 is the water cooled tank, 7 is the molten superalloy, and 8 is the starting zone with a seed.

DESCRIPTION OF THE INVENTION

The apparatus performs as follows: the mold (1) is disposed on the hanger (2) and is fixed on the movable rod (3). The
25 hanger (2), the movable rod (3), and the regulating actuator comprise the drive assembly (14). The mold (1) is placed into the mold preheater furnace (9) with the help of the actuator while regulating the mold position relative to the heater (4). The heat baffle (5) is disposed under the heating zone (10). The top butt end of the water-cooled tank
30 (6) adjoins the baffle's (5) lower surface and is positioned coaxially with

- 4 -

the heater (4) and (11). The vacuum chamber (12) is evacuated to 1×10^{-3} mm m.c. The mold preheating furnace (9) is switched on. Upon reaching the mold temperature of 100-150 °C higher than the liquidus temperature of the alloy being cast, the induction furnace's heater (11) is switched on, the alloy (7) being cast melts and is poured into the heated ceramic mold at the predetermined temperature. After that, the actuator for vertical transportation lowers the mold from the heating zone (10) into the cooling zone (13) at the required rate. Solidification of the molten cast alloy occurs by radiation onto the cold walls of the water-cooled tank. Due to this fact it becomes possible to produce large sized castings with directional and single crystal microstructure. Large size castings can include blades, nozzles, buckets, airfoils, and the like, that are used both in aircraft and land-based turbine engines. The castings are often greater than 30 inches in overall height.

Once the mold with the casting alloy has been lowered along its complete height into the cooling zone, the heater (4 and 11) is switched off. When the temperature is decreased to 300-400 °C, the mold with the solidified casting alloy is extracted from the installation which has been previously decompressed. Then the process is repeated for the next mold.

In another aspect of this invention, in order to produce blades having single crystal structure with desired orientation, a single crystal seed with proper orientation is positioned into the top of the starting zone (8) of the ceramic mold before it is disposed in the vacuum chamber. Then the mold position is strictly fixed relative to the heater. In such event the seed and the solidified portion of the starting zone serve as a cooling medium, and further solidification of the melt is caused by radiation cooling in the water-cooled tank as stated above. The use of the water-cooled tank instead of a chill plate allows the same or better working efficiency of said tank than that of a chill plate or of the prototype circular water-cooled cavity. At the same time the water-cooled tank of this invention does not require the use of a complex drive assembly with airtight seals.

As stated above, the heat baffle (5) is used for raising the axial temperature gradient at the solidification front. Said baffle moves in a horizontal plane, closely adjoins the ceramic mold according to its geometry during the solidification process and consists of the
5 segments or sectors (not less than 2 from each side).

In the inventive apparatus the water-cooled tank may be made of stainless steel and contain a double layer wall surrounding the perimeter of the tank. A vacuum atmosphere is created in the tank to further aid in the cooling of the cast parts. The tank may also
10 effectively function as a mold catch basin in the event of mold breakage, and the expensive, poured casting alloy may be easily removed from the tapered tank and be remelted.

The apparatus of this invention allows one to produce high quality castings having the directional and single crystal structure,
15 including the large sized castings used in the land based turbine industry, by the method of radiation cooling without using the crystallizers of the prior art. The invention also gives the possibility to reconstruct easily the disclosed apparatus for liquid metal cooling crystallization processing, to use successively the invented water-
20 cooled tank as a mold catch basin in the event of mold breakage, and to increase the reliability and economic profitability of the apparatus' performance.
